The mathematics of one-step spectral CT reconstruction methods, one step at a time

Cyril Mory, Simon Rit & Bruno Sixou

11 January 2018

Abstract

5 papers, redoing all the maths with many more intermediate steps than in the original papers, and correcting the mistakes hidden in them. Then implementation in a lightweight matlab framework, and comparisons

1   Introduction

Each section starts with the notations of the paper. These are defined throughout the original papers as the calculations are presented, but having them all available in a single place helps a great deal when trying to re-do the calculations.

2   Synthetic material basis: mu-preconditioning

Section 3.4 of [**?**] proposes to modify the material attenuation matrix μ to speed up and stabilize the internal computations. They call this step "μ-preconditioning", but it can be interpreted as generating a basis of synthetic materials instead of the original materials. These synthetic materials are linear combinations of the original ones, possibly with negative coefficients. We present three ways to choose this basis, i.e. three different μ-preconditionings. Each one provides a matrix P such that $\mu_{\text{real}}P = \mu_{\text{synth}}$:

- Normalizing μ_{real}: each column of μ_{real} is divided by its norm. This has the advantage of not introducing negative attenuations. The added complexity associated with the use of negative attenuation coefficients, like the use of absolute values in the calculation of $\Sigma^{(n)}$ and $T^{(n)}$ in [**?**], can be avoided with this synthetic materials basis

- Orthonormalizing μ_{real}: either using the Gram-Schmidt algorithm or diagonalizing $\mu_{\text{real}}^T\mu_{\text{real}}$ (as proposed in [**?**]), the column of μ_{real} are made orthogonal to each other, in addition to being normalized. This will generate negative attenuation coefficients (for the dot products between columns to be zero)

- Computing
$$Q = \frac{S\mu_{\text{real}}}{S\mathbb{1}} \quad \text{i.e.} \quad (Q)_{b,m} = \frac{\sum_e S_{b,e}\mu_{\text{real}\ \ e,m}}{\sum_e S_{b,e}}$$

  with $S_{b,e}$ the effective spectrum at energy e in bin b, and $\mu_{\text{real}\ \ e,m}$ the attenuation of material m at energy e. Each value $(Q)_{b,m}$ is a weighted mean of the attenuation coefficients of material m over the whole energy spectrum, the weights being the number of photons seen by the detector in bin b. Roughly, it evaluates how much the material m attenuates the photons that will end up being detected in bin b. Now, the problem of determining which linear combination of materials causes the observed attenuation would be much easier if each material attenuated the photons of only one bin, i.e. if Q was diagonal. Therefore, we multiply μ by the inverse of Q, which we denote P. When Q is not square, e.g. when there are more bins that materials, Q cannot be inverted, but P can be defined as the Moore-Penrose pseudo inverse of Q, i.e. $P = (Q^TQ)^{-1}Q^T$, which provides a good replacement for Q^{-1}. This approach was proposed in [**?**] for dual energy CT, but its extension to more materials and more bins is straightforward. The basis created this way has as many synthetic materials as the number of bins, each of which can have negative attenuation coefficients.

3   Cai et al. 2013

The paper [**?**] was originally designed for dual-energy CT with fast kV-switching. Therefore, in the paper, each pixel of the measured data is assumed to contain two values, one for each tube voltage, indexed by u. We adapt the proposed method to spectral CT. u is now used to index the energy bin number. We focus on the discrete model and discard the notations of the continuous model given at the beginning of the paper.
Figure 1: Dependencies between variables in Cai2013

3.1 Notations and intermediate variables

- $u \in \{1..N_v\}$: index of energy bin

- K: total number of pixels, i.e. number of projections $\times$ number of pixels in one projection

- $\varepsilon \in \{1..N_\varepsilon\}$: actual energy of a photon

- $s(u, \varepsilon)$: normalized effective spectrum, i.e. ratio between the number of counts in bin u caused by photons of actual energy ε without object, and the total number of counts in bin u without object

- $\bar{y}(\boldsymbol{t}, u)$: expected beam transmission ratio in pixel $\boldsymbol{t}$ and bin u, i.e. expected ratio between the number of counts with object and without object

- N: number of voxels in a single material volume

- $m \in \{1..n_f\}$: index of basis material

- x: column vector for the object volume. First the volume for material 1, then for material 2, etc...

- A: forward projection matrix for a single material volume

- R: block-diagonal matrix, n_f blocks, each block is a matrix A

- M_1: matrix of material attenuations. Each column of the matrix M_1 is a vector (of height N_ε) containing the attenuation of one material as a function of energy

- M: large matrix, obtained by replacing each value of M_1 by its product with I_K, the identity matrix of size K

- $B = MR$: matrix performing forward projection and computing linear combination with material attenuations. $N \times n_f$ columns and $K \times N_\varepsilon$ rows. Thus, Bx is a column vector of size $K \times N_\varepsilon$, i.e. one volume per energy

- S_1: normalized effective spectrum matrix. One row per bin, one column per energy. Each row sums to 1

- S: large matrix, obtained by replacing each value of S_1 by its product with I_K

- $\bar{y} = S \exp(-Bx)$: column vector of expected beam transmission ratios, of size $K \times N_v$

3.2 Step by step calculations

The authors assume that the variance θ_1 of the measured beam transmission ratios $\bar{y}$ can be known. They also assume a prior on x which results in minimizing the Huber function of the spatial gradient, which is close to the behaviour of anisotropic TV minimization. The dependencies between variables can be summarized in the diagram shown in figure **??**. From this diagram, the following expression of the full joint probability can be inferred:

$$p(x, y, \theta_1, \theta_2) = p(\theta_1)p(\theta_2)p(x|\theta_2)p(y|x, \theta_1)$$

A basic property of the conditional probabilities also gives

$$p(x, y, \theta_1, \theta_2) = p(x, \theta_1|y, \theta_2)p(y, \theta_2)$$
$$= p(x, \theta_1|y, \theta_2)p(y|\theta_2)p(\theta_2)$$

Therefore, equating the right hand sides, we have

$$p(x, \theta_1|y, \theta_2)p(y|\theta_2)p(\theta_2) = p(\theta_1)p(\theta_2)p(x|\theta_2)p(y|x, \theta_1)$$

Simplifying $p(\theta_2)$ and moving $p(y|\theta_2)$ yields equation (20) of [**?**]. Along equations (21) to (24), the authors assume that θ_1, the variance of y, is proportional to y. If $\bar{y}$ is a sufficiently good estimate of y, θ_1 is then also proportional to $\bar{y}$. They note the proportionality factor k_d. It depends on the detector, and can be obtained by calibration. Let us continue with equation (25):

$$\hat{x} = \arg\min_x \left\{ -\log\left[p(y|x, \hat{\theta_1})\right] - \log\left[p(x|\theta_2)\right] \right\}$$

Replacing both probabilities from equations (14) and (17):

$$\hat{x} = \arg\min_x \left\{ -\log \prod_{j=1}^{KN_v} \frac{1}{\sqrt{2\pi\sigma_j^2}} \exp\left\{ -\frac{(y_j - \bar{y}_j)^2}{2\sigma_j^2} \right\} + \Phi(Dx, \theta_2) \right\}$$

$$= \arg\min_x \left\{ \sum_{j=1}^{KN_v} \left[\frac{(y_j - \bar{y}_j)^2}{2\sigma_j^2} - \log\left(\frac{1}{\sqrt{2\pi\sigma_j^2}} \right) \right] + \Phi(Dx, \theta_2) \right\}$$

From equation (24), $\sigma_j^2 = k_d \bar{y}_j$, therefore

$$\hat{x} = \arg\min_x \left\{ \sum_{j=1}^{KN_v} \left[\frac{(y_j - \bar{y}_j)^2}{2k_d\bar{y}_j} + \frac{1}{2}\log 2\pi k_d + \frac{1}{2}\log(\bar{y}_j) \right] + \Phi(Dx, \theta_2) \right\}$$

Removing the term constant with x, multiplying by 2 and cutting the sum into two parts, we obtain

$$\hat{x} = \arg\min_x \left\{ \sum_{j=1}^{KN_v} \frac{(y_j - \bar{y}_j)^2}{k_d\bar{y}_j} + \sum_{j=1}^{KN_v} \log(\bar{y}_j) + 2\Phi(Dx, \theta_2) \right\}$$

The first sum can be compactly written in matrix form. In fact, it is exactly a weighted least squares expression, with weights equal to the inverse of the variance of the measurements. Doing that yields equation (27).

The algorithm employed to minimize the cost function J is a non-linear conjugate gradient. Equations (28) and (29) are standard, the originality here is the choice of the step length $\alpha^{(k)}$, which is explained quite clearly in the paper. In equations (30) and (31), all coefficients of the second degree polynomial in α are scalars, so the calculation is straightforward. The only difficulty is to actually compute g and $d^T H d$. This is done in the appendix. Note that there is a sign error in equation (32). The appendix contains the correct expression of g.

3.3 Modifications for synthetic materials

In the case where the algorithm is fed a matrix M_{synth} of the attenuations of synthetic materials, obtained by linear combination of the attenuations of real materials (the columns of M_{real}), it will reconstruction synthetic material volumes x_{synth}. The expression for the data-attachment term remains correct, but the regularization must be perfomed on the real materials volumes x_{real}, since we want the real material volumes to be regular, not the synthetic ones. To clarify the link between M_{real}, M_{synth}, x_{real} and x_{synth}, let us first imagine that our volumes are made of a single voxel. Let us also note that the total attenuation coefficient for each energy through that volume should be the same, whether we use synthetic or real materials. This condition gives us the following identity:

$$M_{\text{real}}x_{\text{real}} = M_{\text{synth}}x_{\text{synth}}$$

Let P be the matrix such that $M_{\text{real}}P = M_{\text{synth}}$. Then

$$M_{\text{real}}x_{\text{real}} = M_{\text{real}}Px_{\text{synth}}$$
$$\Longleftrightarrow M_{\text{real}}\left(x_{\text{real}} - Px_{\text{synth}}\right) = 0$$

Since the columns of M_{real} are linearly independent by construction (the materials are chosen to have independant attenuation curves), this means $x_{\text{real}} = Px_{\text{synth}}$. So the same matrix is used to transform the real attenuation matrix into the synthetic one and, the other way round, to transform the synthetic volumes into the real ones. In order to apply regularization on real materials, the regularization term J_2, its gradient g_2 and its Hessian H_2 must be replaced by their counterparts adapted to synthetic materials $\widetilde{J}_2$, $\widetilde{g}_2$ and $\widetilde{H}_2$ defined as follows:

$$\widetilde{J}_2(x_{\text{synth}}) = J_2(Px_{\text{synth}}) = 2\Phi(Dx_{\text{real}}, \theta_2)$$
$$\widetilde{g}_2(x_{\text{synth}}) = P^T g_2(Px_{\text{synth}}) = 2P^T D^T \dot{\Phi}(Dx_{\text{real}}, \theta_2)$$
$$\widetilde{H}_2(x_{\text{synth}}) = P^T H_2(Px_{\text{synth}})P = 2P^T D^T \ddot{\Phi}(Dx_{\text{real}}, \theta_2)DP$$

4 Synthetic materials in SQS-based methods

The next three methods work by finding a local quadratic surrogate to the cost function, and minimizing it to obtain the next iterate. In our implementation, the minimization is performed by one iteration of Newton's method, since the Hessian of the surrogate can be computed and inverted quickly. These three SQS-based methods are insensitive to a change of materials basis, probably because Newton's method is. In this section, we prove that Newton's method is insentive to a change of basis. For convenience, we will keep the same notations as in section **??**. Let

$$J : \mathbb{R}^N \mapsto \mathbb{R}$$
$$u \mapsto J(u)$$

be the original cost function, returning the correct result when its input is a set of volumes of the real materials. The cost function for volumes of synthetic materials is

$$\widetilde{J} : \mathbb{R}^N \mapsto \mathbb{R}$$
$$u \mapsto J(Pu)$$

Let $G(x_{\mathrm{real}})$ and $H(x_{\mathrm{real}})$ be the gradient and Hessian of J evaluated at x_{real}, and $\widetilde{G}(x_{\mathrm{synth}})$ and $\widetilde{H}(x_{\mathrm{synth}})$ be the gradient and Hessian of $\widetilde{J}$ evaluated at x_{synth}. From the definition of $\widetilde{J}$, it stems that

$$\widetilde{G}(x_{\mathrm{synth}}) = P^T G(Px_{\mathrm{synth}}) = P^T G(x_{\mathrm{real}})$$
$$\widetilde{H}(x_{\mathrm{synth}}) = P^T H(Px_{\mathrm{synth}})P = P^T H(x_{\mathrm{real}})P$$

For $k \in \mathbb{N}$, let $x_{\mathrm{real}}^{(k)}$ be the k-th iterate obtained by Newton's method when minimizing J, and similarly let $x_{\mathrm{synth}}^{(k)}$ be k-th iterate obtained by Newton's method when minimizing $\widetilde{J}$. Proving that "Newton's method is insensitive to a change of basis" amounts to proving that for any k, $Px_{\mathrm{synth}}^{(k)} = x_{\mathrm{real}}^{(k)}$. Let us do this by mathematical induction. Let $k \in \mathbb{N}$, and assume that $Px_{\mathrm{synth}}^{(k)} = x_{\mathrm{real}}^{(k)}$. From the update step of Newton's method, we have:

$$
\begin{aligned}
x_{\mathrm{synth}}^{(k+1)} &= x_{\mathrm{synth}}^{(k)} - \widetilde{H}(x_{\mathrm{synth}}^{(k)})^{-1}\widetilde{G}(x_{\mathrm{synth}}^{(k)}) \\
&= x_{\mathrm{synth}}^{(k)} - \left(P^T H(x_{\mathrm{real}}^{(k)})P\right)^{-1} P^T G(x_{\mathrm{real}}^{(k)}) \\
&= x_{\mathrm{synth}}^{(k)} - P^{-1} H(x_{\mathrm{real}}^{(k)})^{-1} G(x_{\mathrm{real}}^{(k)}) \\
\implies Px_{\mathrm{synth}}^{(k+1)} &= Px_{\mathrm{synth}}^{(k)} - H(x_{\mathrm{real}}^{(k)})^{-1}G(x_{\mathrm{real}}^{(k)}) \\
Px_{\mathrm{synth}}^{(k+1)} &= x_{\mathrm{real}}^{(k)} - H(x_{\mathrm{real}}^{(k)})^{-1}G(x_{\mathrm{real}}^{(k)}) \\
Px_{\mathrm{synth}}^{(k+1)} &= x_{\mathrm{real}}^{(k+1)}
\end{aligned}
$$

which proves that the property holds for $k+1$ if it holds for k. If one starts from iterates $x_{\mathrm{synth}}^{(0)}$ and $x_{\mathrm{real}}^{(0)}$ such that $Px_{\mathrm{synth}}^{(0)} = x_{\mathrm{real}}^{(0)}$, which is in particular true if both are null, then the property holds for any $k \in \mathbb{N}$. There is therefore no point in changing basis when minimizing a cost function with Newton's method. On the other hand, when minimizing a quadratic cost function with the linear conjugate gradient algorithm, changing basis means preconditioning, and in that case the synthetic and real iterates are not the transform of one another.

5   Long & Fessler 2014

The method described in this paper [?] was designed for a slightly different problem than the one we intend to apply it on: the original goal was to reconstruct three or more materials with only two bins (dual-energy CT measurements), adding enough constraints for that *a priori* ill-posed problem to become tractable. In the present document, we neglect all the constraints and the way they are managed, and keep only the data-attachment and spatial regularization terms.

5.1   Notations and intermediate variables

- M_0: number of bins

- L_0: number of materials

- N_p: number of voxels

- N_d: number of rays (or pixels)

- Y_{im}: measured photon count along ray i in bin m

- $\bar{y}_{im} = \int I_{im}(\varepsilon) \exp\left(- \int_{rayi} \mu(\vec{x}, \varepsilon)dl\right) d\varepsilon + r_{im}$: expected photon count along ray i in bin m, through the current volume estimate

- $I_{im}(\varepsilon)$: effective spectrum at energy ε, ray i and bin m

- r_{im}: photon counts along ray i in bin m with null input spectrum (dark field)

- $\mu(\vec{x}, \varepsilon) = \sum_{l=1}^{L_0} \mu_l(\varepsilon) \sum_{j=1}^{N_p} b_j(\vec{x})x_{lj}$: total attenuation coefficient for energy ε at location $\vec{x}$

- $b_j(\vec{x})$: basis function j at location $\vec{x}$. Using voxels as basis function, b_j is the indicator function of the small cube containing the voxel

- x_{lj}: volume fraction of material l in voxel j

- x: estimate of the reconstructed volume ($x \in \mathbb{R}^{N_p L_0}$)

- A: forward projection matrix

- $s_{il}(x) = [Ax_l]_i = \sum_{j=1}^{N_p} a_{ij} x_{lj}$: line integrals through the material volume x_l, at ray i

- $s_i(x) = (s_{i1}(x), \dots s_{iL_0}(x))$: set of line integrals through all materials Note that in [?], the notation is s_{im}, i.e. the line integrals are assumed to depend on the bin number m. This may be required for dual-energy CT designs other than the "sandwich detector" (i.e. for dual source or fast kV-switching strategies) since, with those designs, low and high energy projections are not acquired along the same path. With spectral photon counting detectors, it becomes irrelevant.

- $z_{im}(s_i(x)) = \int I_{im}(\varepsilon) \exp\left(-\mu(\varepsilon.s_i(\varepsilon)\right) d\varepsilon = \bar{y}_{im}(x) - r_{im}(x)$: "primary" part of $\bar{y}_{im}(x)$

- $h_{im}(s_i(x)) = \log\left(\bar{y}_{im}(s_i(x))\right)$: no physical interpretation. It appears in the negative log-likelihood calculations

- $t_{im}(s_i(x)) = \bar{y}_{im}(s_i(x)) - Y_{im} h_{im}(s_i(x))$: no physical interpretation

- $\bar{L}(x) = \sum_{m=1}^{M_0} \sum_{i=1}^{N_d} t_{im}(s_i(x))$: negative log-likelihood

5.2 A note on the conditions for a function to be a surrogate

Let $\Psi : \mathbb{R} \to \mathbb{R}$ and $\Phi : \mathbb{R} \to \mathbb{R}$ be functions differentiable in $x_0 \in \mathbb{R}$. Φ is a surrogate of Ψ if and only if

$$
\begin{cases}
\forall x \in \mathbb{R}, \Phi(x) \geq \Psi(x) \\
\Phi(x_0) = \Psi(x_0) \\
\Phi'(x_0) = \Psi'(x_0)
\end{cases}
\tag{1}
$$

The condition on the derivative, though, actually stems from the other two, as can be shown using the first order Taylor expansion of Φ and Ψ. Let $h \in \mathbb{R}$. From the first condition, we have:

$$
\begin{aligned}
&\Phi(x_0 + h) \geq \Psi(x_0 + h) \\
\implies &\Phi(x_0) + h\Phi'(x_0) + o(h) \geq \Psi(x_0) + h\Psi'(x_0) + o(h) \\
\iff &h\Phi'(x_0) + o(h) \geq h\Psi'(x_0) + o(h) \text{ since } \Phi(x_0) = \Psi(x_0) \\
\iff &h\left(\Phi'(x_0) - \Psi'(x_0)\right) \geq o(h)
\end{aligned}
\tag{2}
$$

Choosing alternatively $h > 0$ and $h < 0$ and dividing by h yields both $\Phi'(x_0) - \Psi'(x_0) \geq o(1)$ and $\Phi'(x_0) - \Psi'(x_0) \leq o(1)$, which means $\Phi'(x_0) - \Psi'(x_0) = 0$, i.e. $\Phi'(x_0) = \Psi'(x_0)$ This generalizes easily to functions $\mathbb{R}^N \to \mathbb{R}$.

5.3 Step by step calculations

The first surrogate is found by replacing $h_{im}(s_i)$ by its tangent plane, i.e. by its first order Taylor expansion around $s_{im}^{(n)}$. There is nothing to do to get to equations (22) and (23) except replacing the terms from equations (11) and (12) with that from equation (21), and noting that Y_{im} is non-negative, as explained in the paper. The notation $\nabla_{s_i} h_{im}\left(s_i^{(n)}\right)$ means "the gradient of h_{im} with respect to its variable s_i, evaluated at $s_i^{(n)}$". From equation (23), let us develop the parentheses:

$$
\begin{aligned}
f_{1,im}^{(n)}(s_i) &= \bar{y}_{im}(s_i) - Y_{im}\left(h_{im}(s_i^{(n)}) + \nabla_{s_i} h_{im}(s_i^{(n)})(s_i - s_i^{(n)})\right) \\
&= \bar{y}_{im}(s_i) - Y_{im} h_{im}(s_i^{(n)}) - Y_{im} \nabla_{s_i} h_{im}(s_i^{(n)}) s_i + Y_{im} \nabla_{s_i} h_{im}(s_i^{(n)}) s_i^{(n)}
\end{aligned}
$$

The second and fourth terms do not depend on s_i, therefore they can be grouped into a single constant C, yielding the first row of equation (24). Then, the second row is obtained by calculating the gradient of h_{im} evaluated at $s_i^{(n)}$, which is just a matter of derivating a log. From equation (13), we have

$$
\nabla_{s_i} h_{im}(s_i)\Big|_{s_i = s_i^{(n)}} = \nabla_{s_i} \log\left(\bar{y}_{im}(s_i)\right)\Big|_{s_i = s_i^{(n)}}
$$

$$
= \frac{\nabla_{s_i} \bar{y}_{im}(s_i)\Big|_{s_i = s_i^{(n)}}}{\bar{y}_{im}(s_i^{(n)})}
$$

which yields the second row of equation (24). The third row is obtained by replacing twice $\bar{y}_{im}$ with its definition from equation (1). Note that derivating with respect to s_i, a $-\mu(\varepsilon)$ comes out of the exponential, and that $Y_{im}^{(n)}$ is defined right after equation (24). The last row of equation (24) is obtained by grouping both integrals into a single

one, factoring $I_{im}(\varepsilon)$ and using the function f defined in equation (25). This one-dimensional function f has been studied in earlier publications: for any $x \geq 0$, the optimal surrogate of f around x (i.e. the flattest possible parabola that is tangent to the graph of f at x, and above the graph of f everywhere on $\mathbb{R}^+$) is known. And quite suprisingly, it does not depend on α. In the paper, the curvature of that parabola is referred to as "the optimal curvature", and can be found in equations (55) and (56). Equation (26) defines a quadratic surrogate for $f_{1,im}^{(n)}(s_i)$: the zero-th and first order terms are obtained by Taylor expansion of $f_{1,im}^{(n)}$ around $s_i^{(n)}$, and the Hessian is computed from the optimal curvatures along each dimension. The Hessian has L_0 rows and L_0 columns, with L_0 the number of materials. Note that the assumption that the s_i are non-negative is required for the existence of a surrogate of f to be guaranteed. This could have been a problem if we had used a synthetic materials basis for internal computation (see section **??**), but for some reason, using a basis of synthetic materials does not affect convergence of Long2014, so we will simply stick to the original one. Now equation (29) is obtained by summing the surrogates $f_{2,im}^{(n)}$ on all rays and all bins. The paper moves on to finding a voxelwise separable quadratic surrogate $L_3^{(n)}(x)$, derived in details in Appendix C, starting with equation (58). In order to re-do the calculation, let us expand the second row of equation (58) and try to re-obtain $s_i(x)$. Since one divides by π_{ij}, one must assume that it is non zero, except when the numerator (a_{ij}) is also zero, in which case the fraction $\frac{a_{ij}}{p_{ij}}$ is assumed to be zero. Expanding yields

$$\sum_{j=1}^{N_p} \pi_{ij} \left(\frac{a_{ij}}{p_{ij}}(x_j - x_j^{(n)}) + \sum_{j=1}^{N_p} a_{ij}x_j^{(n)} \right) = \sum_{j=1}^{N_p} a_{ij}x_j - \sum_{j=1}^{N_p} a_{ij}x_j^{(n)} + \sum_{j=1}^{N_p} \pi_{ij} \left(\sum_{j=1}^{N_p} a_{ij}x_j^{(n)} \right)$$

Since $\sum_{j=1}^{N_p} a_{ij}x_j^{(n)}$ does not depend on j, it can be taken out of the sum, yielding

$$\sum_{j=1}^{N_p} a_{ij}x_j - \sum_{j=1}^{N_p} a_{ij}x_j^{(n)} + \left(\sum_{j=1}^{N_p} a_{ij}x_j^{(n)} \right) \sum_{j=1}^{N_p} \pi_{ij}$$

If $\sum_{j=1}^{N_p} \pi_{ij} = 1$, this simplifies to

$$\sum_{j=1}^{N_p} a_{ij}x_j - \sum_{j=1}^{N_p} a_{ij}x_j^{(n)} + \sum_{j=1}^{N_p} a_{ij}x_j^{(n)} = \sum_{j=1}^{N_p} a_{ij}x_j = s_i(x)$$

Equation (59) is then the straightforward application of the convexity inequality on $f_{1,im}^{(n)}(s_i(x))$. Then equations (60) and (61) simply remind that $L_3^{(n)}$ has the same value and gradient as $\bar{L}$ around $x^{(n)}$, by construction of the surrogate function, and equation (62) computes the Hessian of $f_{3,j}^{(n)}$, evaluated at x_j.

Finding a surrogate for the regularization term is described in details in sections **??** and **??**, so it will not be developed here.

6 Weidinger et al. 2016

In [**?**], Weidinger *et al.* propose another algorithm based on separable quadratic surrogates of the cost function. Similarly to [**?**], the SQS is derived by successive majorizations: first Q_1 a convex surrogate of the cost function, then Q_2 a quadratic surrogate of Q_1, and finally Q_3 a separable quadratic surrogate of Q_2. It turns out, though, that Q_2 is an approximation of Q_1, not a surrogate ($Q_2(f, f^{(n)})$ can be smaller than $Q_1(f, f^{(n)})$), therefore the algorithm is not entirely rigorous. Yet the method it yields does give good results.

6.1 Notations and intermediate variables

- $i \in \{1..M\}$: index of the pixels in the projection data (or equivalently on the rays, since each ray hits one pixel). Note that from equation (16) on, the M changes for an N. We shall use N, since it is the notation used in most of the paper.

- $b \in \{1..B\}$: index of the energy bins in the projection data

- $j \in \{1..P\}$: index of the voxels in the reconstructed volumes

- $k \in \{1..K\}$: index of the materials in the reconstructed volumes

- E: actual energy of photons, used as integration variable

- $N_{i,0}^b(E)$: number of photons of actual energy E that end up measured in pixel i and energy bin b, when there is no object in the beam

- f: set of sought volumes, one per material

- $f^{(n)}$: estimate of f at iteration n

- f_j^k: concentration of material k in voxel j of f

- N_i^b: number of measured photon counts in pixel i and energy bin b (the measured data). The set of all measured photon counts is simply noted N.

- $\bar{N}_i^b(f)$: expected number of photon counts in pixel i, in energy bin b, when the beam traverses f. The set of all expected photon counts is simply noted $\bar{N}$

- $\mu^k(E)$: attenuation coefficient of material k at energy E

- $L(\bar{N})$: log-likelihood of $\bar{N}$, i.e. this is the log of the probability to measure N photon counts if the expected number of photon counts is $\bar{N}$. Since $\bar{N}$ actually depends only on f, $L(\bar{N})$ and $L(f)$ are used indistinctly

- $\eta = \{\eta^k\}$: regularization parameters

- R: regularization function

- $\Phi(f)$: cost function, composed of $-L(f)$ for the data-attachment term, and $\eta R(f)$ for the regularization term

- $h_i^b(x) = -N_i^b \log(x) + x$: convenient function, at first used to compute the i, b term of $L(\bar{N})$, then to define surrogates Q_1 and Q_2

- $l_i^k(E, f^k) = \sum_{j=1}^P a_{ij} f_j^k \mu^k(E)$: line integral along ray i through material k of f at energy E, i.e. the forward projection of $f^k \mu^k$ at pixel i at energy E

- $l_i(E, f) = \sum_{k=1}^K l_i^k(E, f^k)$: total line integral along ray i at energy E, taking into account all materials

- $t_i(E, f) = \exp(-l_i(E, f))$: attenuation factor caused by f at energy E in the pixel i, i.e. the ratio "number of photons of energy E getting out of the object" divided by "number of photons of energy E getting into the object"

- $\beta_i^{b,(n)}(E) = \frac{\bar{N}_i^b(f^{(n)})}{t_i(E, f^{(n)})}$: no clear physical meaning. Note that the definition of $\beta_i^{b,(n)}(E)$ in equation (13) of [?] is erroneous: $\bar{N}_i^b(f)$ does not depend on E. The second argument is not always mentioned, but it is always $f^{(n)}$. For concision, even when the equations of [?] use the notation $\beta_i^{b,(n)}(E, f^{(n)})$, we shall use $\beta_i^{b,(n)}(E)$ instead in this document.

- $h_i^b(E, l_i) = h_i^b(\exp(-l_i(E, f))\beta_i^{b,(n)}) = N_i^b l_i(E, f) - N_i^b \log(\beta_i^{b,(n)}) + \exp(-l_i(E, f))\beta_i^{b,(n)}$: same function h_i^b as previously, but with different variables, since Jensen's inequality has been applied. Note that the paper uses this notation without defining it, but it is hard to imagine what else it could be.

- $C_i^{b,(n)}$: $K \times K$ curvature matrices for quadratic function $q_i^{b,(n)}$

- $\lambda_{ij}^k\left(E, f_j^k\right) = \frac{a_{ij}\mu^k(E)}{\alpha_{ij}}\left(f_j^k - f_j^{k,(n)}\right) + l_i^{k,(n)}(E)$

6.2 Step by step calculations

6.2.1 Surrogates of the data-attachment term

Start with equation (7), replace the negative exponential with $t_i(E, f)$, and multiply and divide by $\beta_i^{b,(n)}(E)$ to obtain equation (14). Then the paper contains another error: it is h_i^b that is a convex function (and whose convexity is used), not $\bar{N}_i^b(f)$. But let us first prove equation (15):

$$\int \frac{N_{i,0}^b(E)}{\beta_i^{b,(n)}(E)} dE$$

Replacing $\beta_i^{b,(n)}(E)$ by its definition and taking $\bar{N}_i^b(f^{(n)})$ out of the integral since it does not depend on E, we obtain

$$\frac{1}{\bar{N}_i^b(f^{(n)})} \int N_{i,0}^b(E) t_i(E, f^{(n)}) dE$$

and since the integral is equal to $\bar{N}_i^b(f^{(n)})$ from equation (7), it proves equation (15). To prove equation (16), let us first remind Jensen's inequality for convex functions: if h is convex, $\sum_i w_i = 1$ and $\forall i, w_i \geq 0$, then $h\left(\sum_i w_i x_i\right) \leq \sum_i h(x_i)$. It works with a sum, but also with an integral: if h is convex, $\int_E w(E) dE = 1$ and $\forall E, w(E) \geq 0$, then $h\left(\int_E w(E) x(E) dE\right) \leq \int_E h\left(x(E)\right) dE$. Now, start from equation (3) and replace $\bar{N}_i^b(f)$ with equation (14):

$$-L(f) = \sum_{b=1}^B \sum_{i=1}^M h_i^b\left(\int \frac{N_{i,0}^b(E)}{\beta_i^{b,(n)}(E)} t_i(E, f)\beta_i^{b,(n)}(E) dE\right)$$

Applying the integral version of Jensen's inequality with $w(E) = \frac{N_{i,0}^b(E)}{\beta_i^{b,(n)}(E)}$ and $x(E) = t_i(E, f)\beta_i^{b,(n)}(E)$ yields equation (16). Let us assume like in the paper that Q_1 indeed fulfills the conditions to be a surrogate of $-L$ and move on. Equation (17) defines $q_i^{b,(n)}(E, l_i^k)$ which is an abusive notation for $q_i^{b,(n)}\left(E, \{l_i^k\}_{1 \le k \le K}\right)$, meaning that $q_i^{b,(n)}$ does not depend on $l_i(E, f) = \sum_{k=1}^K l_i^k(E, f^k)$, but on the individual l_i^k, for $1 \le k \le K$. $q_i^{b,(n)}$ is defined as a quadratic function equal to the second order Taylor series development of h_i^b around the point $(E, l_i^1, \ldots, l_i^K)$. Why not, but whether or not $q_i^{b,(n)}(E, l_i^k)$ indeed majorizes $h_i^b(E, l_i)$ depends on the choice of the matrices $C_i^{b,(n)}$. For equation (17) to hold at least locally around $(E, l_i^1, \ldots, l_i^K)$, these matrices must be "larger" than the Hessian of $h_i^b(E, l_i)$, i.e. the difference must be a semi-definite positive matrix. Otherwise the higher-order terms could sum up to a negative value and violate equation (17). With the choice stated in the paper, i.e. that the $C_i^{b,(n)}$ be the Hessian of $h_i^b(E, l_i)$, the inequality cannot be guaranteed locally. For Q_2 to be a surrogate, equation (17) should also hold globally, i.e. for all f, but this can only be obtained assuming that the l_i^k are positive. This can be found in [?], where Erdogan & Fessler assume that the l_i^k are positive (equation (9) in [?]), and calculate the optimal curvatures, i.e. the "smallest" $C_i^{b,(n)}$ matrices for which equation (17) holds for all $l_i^k \ge 0$. Here, Weidinger et al. note that assuming non-negativity of the line integrals can prevent accurate reconstruction of materials that are not in the decomposition basis: those are represented by linear combinations of the basis materials, potentially with negative coefficients, which can make the line integrals negative. So they do not make the non-negativity assumption, and therefore cannot find an optimal curvature. Thus, with the choice made in the paper, equation (17) holds neither locally nor globally, and the inequality sign should be replaced by an approximation sign. One could add εI, with $\varepsilon \ge 0$, to the Hessian of $h_i^b(E, l_i)$, and thus obtain $C_i^{b,(n)}$ matrices that at least guarantee equation (17) locally. But let's continue anyway and find a surrogate Q_3 for Q_2, leaving aside that Q_2 is not a surrogate for Q_1. To obtain Q_3, we need to use the convexity of $q_i^{b,(n)}$, writing its argument as a weighted sum, with weights adding up to 1. Let's start in equation (20), by rewriting $l_i^k\left(E, f^k\right)$:

$$l_i^k\left(E, f^k\right) = \sum_{j=1}^P a_{ij} f_j^k \mu^k(E)$$

Adding and subtracting $l_i^k\left(E, f^{(n)}\right)$, compactly noted $l_i^{k,(n)}(E)$, we get

$$l_i^k\left(E, f^k\right) = \sum_{j=1}^P a_{ij} f_j^k \mu^k(E) - l_i^{k,(n)}(E) + l_i^{k,(n)}(E)$$

And we write one of the $l_i^{k,(n)}(E)$ as a sum, simply using its definition:

$$l_i^k\left(E, f^k\right) = \sum_{j=1}^P a_{ij} f_j^k \mu^k(E) - \sum_{j=1}^P a_{ij} f_j^{k,(n)} \mu^k(E) + l_i^{k,(n)}(E)$$

Then factor the two sums:

$$l_i^k\left(E, f^k\right) = \sum_{j=1}^P a_{ij} \mu^k(E) \left(f_j^k - f_j^{k,(n)}\right) + l_i^{k,(n)}(E)$$

In the sum, we divide and multiply by $\alpha_{ij} = \frac{a_{ij}}{\sum_{j=1}^P a_{ij}}$, and outside the sum, we multiply $l_i^{k,(n)}(E)$ by one

$$l_i^k\left(E, f^k\right) = \sum_{j=1}^P \frac{\alpha_{ij}}{\alpha_{ij}} a_{ij} \mu^k(E) \left(f_j^k - f_j^{k,(n)}\right) + \left(\sum_{j=1}^P \alpha_{ij}\right) l_i^{k,(n)}(E)$$

Since $l_i^{k,(n)}(E)$ does not depend on j, it can enter the sum. Merging all sums yields the second line of equation (20), and the third line is just the definition of $\lambda_{ij}^k\left(E, f_j^k\right)$. Equation (23) is then obtained simply by applying Jensen's inequality from equation (19).

6.2.2 Surrogate of the regularization term

Equation (24) then gives the surrogate of the regularization term. Here, we will detail the calculations for a generic regularization term of the form proposed in equation (4). By "generic", we mean that any relevant convex twice-differentiable and even function ψ can be used. We then calculate the first and second derivatives of the Huber function and of the hyperbola used in [?]. The Green's function (used in Weidinger's paper) [?] and its derivatives are left to the reader. Here we only consider a single material, but extension to several materials is straightforward, using a function Ψ that sums the values obtained by the individual $\psi's$ for each material. Repeating the argument in equation (9) of [?], we start by writing:

$$\psi(f_j - f_l) = \psi\left(\frac{1}{2}[2f_j - f_j^n - f_l^n] + \frac{1}{2}[-2f_l + f_j^n + f_l^n]\right)$$

Using the fact that ψ is convex, we get

$$\psi(f_j - f_l) \le \frac{1}{2}\psi(2f_j - f_j^n - f_l^n) + \frac{1}{2}\psi(-2f_l + f_j^n + f_l^n)$$

And since ψ is even,

$$\psi(f_j - f_l) \le \frac{1}{2}\psi(2f_j - f_j^n - f_l^n) + \frac{1}{2}\psi(2f_l - f_j^n - f_l^n)$$

And therefore

$$\sum_{j=1}^{P}\sum_{l\in N_j}\psi(f_j - f_l) \le \frac{1}{2}\sum_{j=1}^{P}\sum_{l\in N_j}\left[\psi(2f_j - f_j^n - f_l^n) + \psi(2f_l - f_j^n - f_l^n)\right] = R(f, f^n)$$

So we have a surrogate for the regularization term. Let us now compute its gradient and Hessian.

$$\frac{\partial R(f, f^n)}{\partial f_{j_0}} = \frac{1}{2}\sum_{j=1}^{P}\sum_{l\in N_j}\left[\frac{\partial}{\partial f_{j_0}}\psi(2f_j - f_j^n - f_l^n) + \frac{\partial}{\partial f_{j_0}}\psi(2f_l - f_j^n - f_l^n)\right]$$

In the brackets, the first term is non-zero only when $j = j_0$. The second term is non-zero only when $l = j_0$. For a given value of j, if the neighborhood N_j contains j_0, that term remains, otherwise it gives zero. The tricky part is to determine when the neighborhood N_j contains j_0, i.e. what is the set of indices j such that N_j contains j_0. From a simple drawing with a non-symmetrical neighborhood, it can be shown that this set is the symmetrical of N_{j_0} with respect to j_0, which could be noted $\bar{N}_{j_0}$. Since one always uses neighborhoods with a symmetrical shape, in our case $\bar{N}_{j_0} = N_{j_0}$. With all these considerations, the sums on j disappear, and we are left with

$$\frac{\partial R(f, f^n)}{\partial f_{j_0}} = \frac{1}{2}\left(\sum_{l\in N_{j_0}}\frac{\partial}{\partial f_{j_0}}\psi(2f_{j_0} - f_{j_0}^n - f_l^n) + \sum_{j\in N_{j_0}}\frac{\partial}{\partial f_{j_0}}\psi(2f_{j_0} - f_j^n - f_{j_0}^n)\right)$$

Both terms are identical, so we can merge them and remove the factor $1/2$. Using the notation $\dot\psi$ for the first derivative of ψ, and accounting for the factor 2 that comes out of ψ when derivating, we end up with

$$\frac{\partial R(f, f^n)}{\partial f_{j_0}} = 2\sum_{j\in N_{j_0}}\dot\psi(2f_{j_0} - f_j^n - f_{j_0}^n)$$

That's for the gradient of the surrogate of the regularization term. Now for the Hessian:

$$\frac{\partial^2 R(f, f^n)}{\partial f_{j_0}\partial f_{j_1}} = 2\sum_{j\in N_{j_0}}\frac{\partial}{\partial f_{j_1}}\dot\psi(2f_{j_0} - f_j^n - f_{j_0}^n)$$

The term in the sum is non-null only when $j_1 = j_0$, making the Hessian diagonal. Note that the sum is on j, not j_0 or j_1, so it does not disappear by differentiation. We are left with

$$\frac{\partial^2 R(f, f^n)}{\partial f_{j_0}\partial f_{j_1}} = 4\delta(j_0, j_1)\sum_{j\in N_{j_0}}\ddot\psi(2f_{j_0} - f_j^n - f_{j_0}^n)$$

Both the gradient and the Hessian will always be evaluated at $f = f^{(n)}$, and will therefore result in

$$\left.\frac{\partial R(f, f^n)}{\partial f_{j_0}}\right|_{f=f^{(n)}} = 2\sum_{j\in N_{j_0}}\dot\psi(f_{j_0}^n - f_j^n) \quad\text{and}\quad \left.\frac{\partial^2 R(f, f^n)}{\partial f_{j_0}\partial f_{j_1}}\right|_{f=f^{(n)}} = 4\delta(j_0, j_1)\sum_{j\in N_{j_0}}\ddot\psi(f_{j_0}^n - f_j^n)$$

6.2.3 Derivatives of the Huber function

The Huber function is defined in equation (18) of [**?**] as follows:

$$H_\delta(x) = \begin{cases} x^2 & \text{for } |x| \le \delta, \\ 2\delta|x| - \delta^2, & \text{otherwise.} \end{cases}$$

Its first and second derivatives are

$$\dot H_\delta(x) = \begin{cases} 2x & \text{for } |x| \le \delta, \\ 2\delta\,\text{sign}(x), & \text{otherwise.} \end{cases} \qquad\qquad \ddot H_\delta(x) = \begin{cases} 2 & \text{for } |x| \le \delta, \\ 0, & \text{otherwise.} \end{cases}$$

6.2.4 Derivatives of the hyperbola function defined in Long2014

[?] defines a hyperbola function in equation (18) as follows:

$$H_\delta(x) = \frac{\delta^2}{3}\left(\left(1 + 3\left(\frac{x}{\delta}\right)^2\right)^{\frac{1}{2}} - 1\right)$$

Its first and second derivatives are

$$\dot{H}_\delta(x) = x\left(1 + 3\left(\frac{x}{\delta}\right)^2\right)^{-\frac{1}{2}} \qquad\qquad \ddot{H}_\delta(x) = \left(1 + 3\left(\frac{x}{\delta}\right)^2\right)^{-\frac{3}{2}}$$

6.2.5 Minimizing these surrogates

Let us now move on to proving equation (26). The paper abusively uses variables j and k both inside and outside of sums, we shall use j and k inside sums and j_0 and k_0 outside:

$$\left.\frac{\partial Q_3\left(f, f^{(n)}\right)}{\partial f_{j_0}^{k_0}}\right|_{f=f^{(n)}} = \left.\frac{\partial}{\partial f_{j_0}^{k_0}}\left[\sum_{b=1}^{B}\sum_{i=1}^{N}\sum_{j=1}^{P}\int \frac{N_{i,0}^b(E)}{\beta_i^{b,(n)}(E)}\alpha_{ij}q_i^{b,(n)}\left(E, \lambda_{ij}^k\left(E, f_j^k\right)\right) dE\right]\right|_{f=f^{(n)}}$$

Since $\frac{N_{i,0}^b(E)}{\beta_i^{b,(n)}(E)}\alpha_{ij}$ does not depend on $f_{j_0}^{k_0}$, we only have to compute $\frac{\partial}{\partial f_{j_0}^{k_0}}\left[q_i^{b,(n)}\left(E, \lambda_{ij}^k\left(E, f_j^k\right)\right)\right]$. This is still difficult, but something else helps: we do not need the general expression of $\frac{\partial}{\partial f_{j_0}^{k_0}}\left[q_i^{b,(n)}\left(E, \lambda_{ij}^k\left(E, f_j^k\right)\right)\right]$, we only need it evaluated at $f = f^{(n)}$ (see equation (26)). Note that equation (26) contains $\frac{\partial \bar{N}_i^{b,(n)}}{\partial f_{j_0}^{k_0}}$, which seems to be an abuse of notation for $\left.\frac{\partial \bar{N}_i^b(f)}{\partial f_{j_0}^{k_0}}\right|_{f=f(n)}$, since $\bar{N}_i^{b,(n)} = \bar{N}_i^b(f^{(n)})$, which does not depend on $f_{j_0}^{k_0}$, and therefore the gradient would always be zero.

From the definition of $q_i^{b,(n)}$, the zero-order term cancels out while differentiating, and the second-order term leaves a factor $l_i^{k_0} - l_i^{k_0,(n)}$, which cancels out when evaluated at $f = f^{(n)}$. Therefore only the first-order term is left

$$\frac{\partial}{\partial f_{j_0}^{k_0}}\left[q_i^{b,(n)}\left(E, \lambda_{ij}^k\left(E, f_j^k\right)\right)\right] = \frac{\partial}{\partial f_{j_0}^{k_0}}\left[\sum_{k=1}^{K}\left.\frac{\partial h_i^b(E, l_i)}{\partial l_i^k}\right|_{l_i^k=l_i^{k,(n)}}(\lambda_{ij}^k(E, f_j^k) - l_i^{k,(n)})\right]$$

From the sum over k, only the term in k_o remains, and the derivative evaluated in $l_i^k = l_i^{k,(n)}$ does not vary with $f_{j_0}^{k_0}$, therefore

$$\frac{\partial}{\partial f_{j_0}^{k_0}}\left[q_i^{b,(n)}\left(E, \lambda_{ij}^k\left(E, f_j^k\right)\right)\right] = \left.\frac{\partial h_i^b(E, l_i)}{\partial l_i^k}\right|_{l_i^k=l_i^{k,(n)}}\frac{\partial}{\partial f_{j_0}^{k_0}}(\lambda_{ij}^{k_0}(E, f_{j_0}^{k_0}) - l_i^{k_0,(n)})$$

Taking each bit at a time:

$$\frac{\partial h_i^b(E, l_i)}{\partial l_i^k} = \frac{\partial}{\partial l_i^k}\left[-N_i^b \log\left(t_i(E, f)\beta_i^{b,(n)}(E)\right) + t_i(E, f)\beta_i^{b,(n)}(E)\right]$$

$$= -\frac{N_i^b}{t_i(E, f)}\frac{\partial t_i(E, f)}{\partial l_i^k} + \beta_i^{b,(n)}(E)\frac{\partial t_i(E, f)}{\partial l_i^k}$$

Since $t_i(E, f) = \exp(-\sum_{k=1}^{K} l_i^k(E, f^k))$, its derivative with respect to l_i^k is simply $-t_i(E, f)$. Replacing in the above equation, this yields

$$\frac{\partial h_i^b(E, l_i)}{\partial l_i^k} = N_i^b - \beta_i^{b,(n)}(E)t_i(E, f)$$

Evaluated at $f = f^{(n)}$, this gives

$$\left.\frac{\partial h_i^b(E, l_i)}{\partial l_i^k}\right|_{l_i^k=l_i^{k,(n)}} = N_i^b - \bar{N}_i^{b,(n)}$$

And now for the second bit (only the terms in j_0 and k_0 remain from the various sums)

$$\frac{\partial}{\partial f_{j_0}^{k_0}}\left[\lambda_{ij_0}^{k_0}(E, f_{j_0}^{k_0}) - l_i^{k_0,(n)}\right] = \frac{\partial}{\partial f_{j_0}^{k_0}}\left[\frac{a_{ij_0}\mu^{k_0}(E)}{\alpha_{ij_0}}\left(f_{j_0}^{k_0} - f_{j_0}^{k_0,(n)}\right)\right]$$

$$= \frac{a_{ij_0}\mu^{k_0}(E)}{\alpha_{ij_0}}$$

Back to the derivative of equation (23), and replacing both bits by what we computed:

$$\frac{\partial Q_3\left(f, f^{(n)}\right)}{\partial f_{j_0}^{k_0}}\bigg|_{f=f^{(n)}} = \sum_{b=1}^{B}\sum_{i=1}^{N}\int \frac{N_{i,0}^{b}(E)}{\beta_i^{b,(n)}(E)}\alpha_{ij_0}\left(N_i^b - \bar{N}_i^b(f^{(n)})\right)\frac{a_{ij_0}\mu^{k_0}(E)}{\alpha_{ij_0}}dE$$

The α_{ij_0} simplify, the difference $N_i^b - \bar{N}_i^b(f^{(n)})$ gets out of the integral, and we are left with

$$\frac{\partial Q_3\left(f, f^{(n)}\right)}{\partial f_{j_0}^{k_0}}\bigg|_{f=f^{(n)}} = \sum_{b=1}^{B}\sum_{i=1}^{N}\left(N_i^b - \bar{N}_i^b(f^{(n)})\right)\int \frac{N_{i,0}^{b}(E)}{\beta_i^{b,(n)}(E)}a_{ij_0}\mu^{k_0}(E)dE$$

The integral looks similar to what one would obtain by differentiating $\bar{N}_i^b$ with respect to $f_{j_0}^{k_0}$, which is suggested in equation (26), so let us calculate that independently and see what comes out:

$$\frac{\partial \bar{N}_i^b(f)}{\partial f_{j_0}^{k_0}} = \frac{\partial}{\partial f_{j_0}^{k_0}}\int N_{i,0}^{b}(E)\exp\left(-\sum_{j=1}^{P}a_{ij}\sum_{k=1}^{K}f_j^k\mu^k(E)\right)dE$$

$$= \int N_{i,0}^{b}(E)\frac{\partial}{\partial f_{j_0}^{k_0}}\exp\left(-\sum_{j=1}^{P}a_{ij}\sum_{k=1}^{K}f_j^k\mu^k(E)\right)dE$$

$$= -\int N_{i,0}^{b}(E)a_{ij_0}\mu^{k_0}(E)\exp\left(-\sum_{j=1}^{P}a_{ij}\sum_{k=1}^{K}f_j^k\mu^k(E)\right)dE$$

Evaluated at $f = f^{(n)}$, this yields

$$\frac{\partial \bar{N}_i^b(f)}{\partial f_{j_0}^{k_0}}\bigg|_{f=f^{(n)}} = -\int N_{i,0}^{b}(E)a_{ij_0}\mu^{k_0}(E)t_i\left(E, f^{(n)}\right)dE$$

$$= -\int N_{i,0}^{b}(E)a_{ij_0}\mu^{k_0}(E)\frac{\bar{N}_i^b(f^{(n)})}{\beta_i^{b,(n)}(E)}dE$$

$$= -\bar{N}_i^b(f^{(n)})\int \frac{N_{i,0}^{b}(E)}{\beta_i^{b,(n)}(E)}a_{ij_0}\mu^{k_0}(E)dE$$

We find the same integral as before, and the $-\bar{N}_i^b(f^{(n)})$ factor can be extracted, finally yielding (26). And now let's go for the Hessian of Q_3, simply differentiating equation (23) twice. From the sums over j, k and m, only the terms in j_0, k_0 and m_0 remain:

$$\frac{\partial^2 Q_3}{\partial f_{j_0}^{k_0}\partial f_{j_0}^{m_0}} = \sum_{b=1}^{B}\sum_{i=1}^{N}\sum_{j=1}^{P}\int \frac{N_{i,0}^{b}(E)}{\beta_i^{b,(n)}(E)}\alpha_{ij}\frac{\partial^2}{\partial f_{j_0}^{k_0}\partial f_{j_0}^{m_0}}\left[q_i^{b,(n)}\left(E, \lambda_{ij}^k\left(E, f_j^k\right)\right)\right]dE$$

Let us compute separately the second derivative of $q_i^{b,(n)}$. From the definition of $q_i^{b,(n)}$ in equation (18), only the second-order term remains, and the factor $\frac{1}{2}$ is removed because all terms appear twice. Therefore:

$$\frac{\partial^2}{\partial f_{j_0}^{k_0}\partial f_{j_0}^{m_0}}\left[q_i^{b,(n)}\left(E, \lambda_{ij}^k\left(E, f_j^k\right)\right)\right] = C_i^{bk_0m_0,(n)}\frac{\partial^2}{\partial f_{j_0}^{k_0}\partial f_{j_0}^{m_0}}\left[\frac{a_{ij_0}\mu^{k_0}}{\alpha_{ij_0}}\left(f_{j_0}^{k_0} - f_{j_0}^{k_0,(n)}\right)\frac{a_{ij_0}\mu^{m_0}}{\alpha_{ij_0}}\left(f_{j_0}^{m_0} - f_{j_0}^{m_0,(n)}\right)\right]$$

$$= C_i^{bk_0m_0,(n)}\frac{a_{ij_0}^2}{\alpha_{ij_0}^2}\mu^{k_0}\mu^{m_0}$$

which gives equation (27). The paper then suggests using the coefficients of the Hessian $\frac{\partial^2 h_i^b(E, l_i)}{\partial l_i^{k_0}\partial l_i^{m_0}}$ instead of the $C_i^{bk_0m_0,(n)}$ coefficients. So let us first compute that Hessian:

$$\frac{\partial^2 h_i^b(E, l_i)}{\partial l_i^{k_0}\partial l_i^{m_0}} = \frac{\partial}{\partial l_i^{m_0}}\left[\frac{\partial h_i^b(E, l_i)}{\partial l_i^k}\right]$$

$$= \frac{\partial}{\partial l_i^{m_0}}\left[N_i^b - \beta_i^{b,(n)}(E)t_i(E, f)\right]$$

$$= \beta_i^{b,(n)}(E)t_i(E, f)$$

Evaluated at $f = f^{(n)}$, this yields

$$\frac{\partial^2 h_i^b(E, l_i)}{\partial l_i^{k_0}\partial l_i^{m_0}} = \beta_i^{b,(n)}(E)t_i(E, f^{(n)})$$

$$= \bar{N}_i^{b,(n)}$$

which yields the first line of equation (28), except that the N_i^b is actually an $\bar{N}_i^{b,(n)}$. The next line of equation (28) is obtained by just replacing α_{ij_0} and $\beta_i^{b,(n)}$ with their definitions, but the ratio between N_i^b and $\bar{N}_i^{b,(n)}$ should be replaced by one. So equation (28) should actually read

$$\frac{\partial^2 Q_3}{\partial f_{j_0}^{k_0} \partial f_{j_0}^{m_0}} = \sum_{b=1}^{B} \sum_{i=1}^{N} a_{ij_0} \left(\sum_{j=1}^{P} a_{ij} \right) \int N_{i,0}^b(E) \mu^{k_0}(E) \mu^{m_0}(E) t_i(E, f^{(n)}) dE$$

To finish, note that in the summary of the algorithm, at step (3), there is a minus sign missing. Taking into account that, plus the abuse of notation already mentioned, equation (30) should read

$$\int N_{i,0}^b(E) \mu^{k_0}(E) t_i(E, f^{(n)}) dE = -\frac{1}{a_{ij_0}} \frac{\partial \bar{N}_i^b(f)}{\partial f_{j_0}^{k_0}} \Bigg|_{f=f(n)}$$

6.2.6 Modifications for synthetic materials

In Weidinger2016 too, in the case where the algorithm is fed a matrix M_{synth} of the attenuations of synthetic materials, we want the real material volumes to be regular, not the synthetic ones. Let P be the matrix such that $PM_{\text{real}} = M_{\text{synth}}$ and $Px_{\text{synth}} = x_{\text{real}}$. Most of the calculations of section ?? are trivially updated by inserting matrix P, and replacing the one-dimensional ψ by a multi-dimensional Ψ, such that $\Psi(\boldsymbol{x}) = \sum_{k=1}^{K} \psi(x_k)$. The main changes are:

$$R(f, f^n) = \frac{1}{2} \sum_{j=1}^{P} \sum_{l \in N_j} \left[\Psi \left(P[2f_j - f_j^n - f_l^n] \right) + \Psi \left(P[2f_l - f_j^n - f_l^n] \right) \right]$$

$$\frac{\partial R(f, f^n)}{\partial f_{j_0}} \Bigg|_{f=f^{(n)}} = 2 \sum_{j \in N_{j_0}} P^T \dot{\Psi} \left(P[f_{j_0}^n - f_j^n] \right)$$

$$\frac{\partial^2 R(f, f^n)}{\partial f_{j_0} \partial f_{j_1}} \Bigg|_{f=f^{(n)}} = 4\delta(j_0, j_1) P^T \sum_{j \in N_{j_0}} \ddot{\Psi} \left(P[f_{j_0}^n - f_j^n] \right) P$$

7 Mechlem 2017

This paper [?] builds upon Weidinger et al. [?], adding three main features:

- A calibration algorithm, when the effective spectrum is not known (or not known with enough precision)

- Ordered Subsets (OS)

- Nesterov acceleration

In addition to that, it suggests to compute the Hessian (and its inverse) only once, thus updating only the gradient at each iteration. This approach is only valid if the Hessian is near-constant, i.e. if the estimated volume undergoes little change over the course of the iterations. Thus it is proposed to start the iterations from a previously known approximate result, like a two-steps reconstruction. Since we start from a zero-filled estimate, we do not use this acceleration.

7.1 Calibration

7.2 Ordered Subsets

There is nothing specific to one-step in the way OS should be handled here.

7.3 Nesterov

The formulas given in Table 1 can be simplified to get rid of the sums. Independently of the OS part, the Nesterov update step used in the paper is the following:

$$t_{k+1} = \frac{1}{2} \left(1 + \sqrt{1 + 4t_k^2} \right)$$

$$\vec{\alpha}^{(k+1)} = \vec{z}^{(k)} - (H_\varphi)^{-1} . \nabla_{S_m} \theta \left(\vec{z}^{(k)} \right)$$

$$\vec{v}^{(k+1)} = \vec{z}^{(0)} - \sum_{l=0}^{k} t_l (H_\varphi)^{-1} . \nabla_{S_m} \theta \left(\vec{z}^{(l)} \right)$$

$$\vec{z}^{(k+1)} = \vec{\alpha}^{(k+1)} + \frac{t_{k+1}}{\sum_{l=0}^{k+1} t_l} \left(\vec{v}^{(k+1)} - \vec{\alpha}^{(k+1)} \right)$$

Note that in the equations of the paper, it is assumed that the Hessian is not recomputed at each iteration, therefore the Hessian is noted H_φ. That the Hessian stays constant is not a requirement for Nesterov acceleration, and given the choice we have made (start from a zero-filled estimate), we will keep $H_\varphi^{(k)}$ instead. The key to simplify these equations is to first define

$$\vec{g}^{(k)} = \left(H_\varphi^{(k)}\right)^{-1} . \nabla_{S_m} \theta\left(\vec{z}^{(k)}\right)$$

which yields

$$\vec{\alpha}^{(k+1)} = \vec{z}^{(k)} - \vec{g}^{(k)}$$

$$\vec{v}^{(k+1)} = \vec{z}^{(0)} - \sum_{l=0}^{k} t_l \vec{g}^{(l)}$$

and then to compute

$$\vec{v}^{(k+1)} - \vec{v}^{(k)} = \left(\vec{z}^{(0)} - \sum_{l=0}^{k} t_l \vec{g}^{(l)}\right) - \left(\vec{z}^{(0)} - \sum_{l=0}^{k-1} t_l \vec{g}^{(l)}\right)$$

$$= -t_k \vec{g}^{(k)}$$

Combining these changes, the Nesterov update step is

$$t_{k+1} = \frac{1}{2}\left(1 + \sqrt{1 + 4t_k^2}\right)$$

$$\vec{g}^{(k)} = \left(H_\varphi^{(k)}\right)^{-1} . \nabla_{S_m} \theta\left(\vec{z}^{(k)}\right)$$

$$\vec{\alpha}^{(k+1)} = \vec{z}^{(k)} - \vec{g}^{(k)}$$

$$\vec{v}^{(k+1)} = \vec{v}^{(k)} - t_k \vec{g}^{(k)}$$

$$\vec{z}^{(k+1)} = \vec{\alpha}^{(k+1)} + \frac{t_{k+1}}{\sum_{l=0}^{k+1} t_l}\left(\vec{v}^{(k+1)} - \vec{\alpha}^{(k+1)}\right)$$

8   Barber 2016

Roughly, the algorithm proposed in [?] is a modified Chambolle-Pock designed to minimize a difference of convex functions, called MOCCA [?]. The mathematics of MOCCA are beyond my reach, therefore this section focuses on making the algorithm described in equations (47)-(52) of [?] easy to implement.

The main difficulty is to compute the matrix $K_1(f_0)$, which depends on f_0, and therefore changes at each iteration. $K_1(f_0)$ has $N_w N_l$ rows and $N_k N_m$ columns, i.e. it is and is $N_w N_m$ times larger than the forward projection matrix X, which makes it impossible to store for real reconstruction situations. In equations (16) and (17), the matrices Z and A are defined with multiple indices. As explained in appendix B, $A_{wl,l'i}$ means $A_{s,t}$, where $s = w.N_l + l$ and $t = i.N_l + l'$, which means that A is organized in $w \times i$ blocks of size $N_l \times N_l$. However, another organization of A can be chosen, provided it is consistent with the organization of Z, f, etc ... We recommend to use $s = l.N_w + w$ and $t = l'.N_i + i$, since then $l' = l$ yields a block-diagonal matrix A. Each block is of size $w \times i$, and processes one (multiple-energy) pixel of the input vector. Corresponding choices for Z and f are $Z_{li,mk} = Z_{l.N_i+i,k.N_m+m}$ and $f_{km} = f_{k.N_m+m}$. In short, they mean "all materials of a voxel, then the next voxel" and "all energies of a pixel, then the next pixel". Computing Zf can be implemented with one forward projection per material of f, then for each (multi-material) pixel, multiplication by the matrix μ. Note that Zf is a vector of size $N_l N_i$. If all energies of the input spectrum (typically about a hundred) are used, it may be too large to store. In that case, it would be preferable to compute one pixel of Zf at a time, and compute the multiplication by A of that pixel, then move to the next one. Multiplication by A can be performed pixel by pixel, by generating for each pixel the corresponding $w \times i$ block and multiplying with it. Let us now comment the equations of the algorithm:

- Equation (48) defines $\Sigma^{(n)}$ and $T^{(n)}$, which are the dual and primal step sizes, respectively. They are diagonal matrices, but Σ should be stored as a set of multi-bin projections, and T as a multi-material volume. Multiplying by them results in a simple pixelwise (for Σ) or voxelwise (for T) multiplication, and multiplying by their inverse is equivalent to dividing pixelwise or voxelwise. The same holds for D_1, r, r_- and b, which should all be stored as multi-bin projections

- Equation (52) can probably be generalized to $\bar{f}^{(n+1)} = f^{(n+1)} + \theta\left(f^{(n+1)} - f^{(n)}\right)$, as in the original Chambolle-Pock algorithm (see e.g. Equation (7) of [?]), where $\theta \in [0; 1]$. In our experiments, using $\theta = 0$ led to slower convergence, but reduced the risk of accidental divergence.
